ABOUT THE TECHNOLOGY ASSESSMENT PROGRAM

The Technology Assessment Program is sponsored by the Office of Development, Testing, and Dissemination of the National Institute of Justice (NIJ), U.S. Department of Justice. The program responds to the mandate of the Justice System Improvement Act of 1979, which created NIJ and directed it to encourage research and development to improve the criminal justice system and to disseminate the results to Federal, State, and local agencies.

The Technology Assessment Program is an applied research effort that determines the technological needs of justice system agencies, sets minimum performance standards for specific devices, tests commercially available equipment against those standards, and disseminates the standards and the test results to criminal justice agencies nationwide and internationally.

The program operates through:

The *Technology Assessment Program Advisory Council* (TAPAC) consisting of nationally recognized criminal justice practitioners from Federal, State, and local agencies, which assesses technological needs and sets priorities for research programs and items to be evaluated and tested.

The *Law Enforcement Standards Laboratory* (LESL) at the National Bureau of Standards, which develops voluntary national performance standards for compliance testing to ensure that individual items of equipment are suitable for use by criminal justice agencies. The standards are based upon laboratory testing and evaluation of representative samples of each item of equipment to determine the key attributes, develop test methods, and establish minimum performance requirements for each essential attribute. In addition to the highly technical standards, LESL also produces user guides that explain in nontechnical terms the capabilities of available equipment.

The *Technology Assessment Program Information Center* (TAPIC), operated by a grantee, which supervises a national compliance testing program conducted by independent agencies. The standards developed by LESL serve as performance benchmarks against which commercial equipment is measured. The facilities, personnel, and testing capabilities of the independent laboratories are evaluated by LESL prior to testing each item of equipment, and LESL helps the Information Center staff review and analyze data. Test results are published in Consumer Product Reports designed to help justice system procurement officials make informed purchasing decisions.

Publications issued by the National Institute of Justice, including those of the Technology Assessment Program, are available from the National Criminal Justice Reference Service (NCJRS), which serves as a central information and reference source for the Nation's criminal justice community. For further information, or to register with NCJRS, write to the National Institute of Justice, National Criminal Justice Reference Service, Washington, DC 20531.

ACKNOWLEDGMENTS

This report was prepared by the Law Enforcement Standards Laboratory (LESL) of the National Bureau of Standards (NBS) under the direction of Marshall J. Treado, Communications Systems Program Manager, and Lawrence K. Eliason, Chief of LESL. The author appreciates the help of Ramon L. Jesch, NBS Electromagnetic Fields Division member, who performed all of the network analyzer measurements and assisted in the antenna impedance and gain measurement program.

FOREWORD

The Law Enforcement Standards Laboratory (LESL) of the National Bureau of Standards (NBS) furnishes technical support to the National Institute of Justice (NIJ) program to strengthen law enforcement and criminal justice in the United States. LESL's function is to conduct research that will assist law enforcement and criminal justice agencies in the selection and procurement of quality equipment.

LESL is: 1) Subjecting existing equipment to laboratory testing and evaluation and 2) conducting research leading to the development of several series of documents, including national voluntary equipment standards, user guides, and technical reports.

This document covers research on law enforcement equipment conducted by LESL under the sponsorship of NIJ. Additional reports as well as other documents are being issued under the LESL program in the areas of protective equipment, communications equipment, security systems, weapons, emergency equipment, investigative aids, vehicles, and clothing.

Technical comments and suggestions concerning this report are invited from all interested parties. They may be addressed to the Law Enforcement Standards Laboratory, National Bureau of Standards, Gaithersburg, MD 20899.

MONOPOLE IMPEDANCE AND GAIN MEASUREMENTS OF FINITE GROUND PLANES

R. G. FitzGerrell*

National Bureau of Standards, Boulder, CO 80303

The purpose of the work described in this report is to determine if it is possible to make acceptably accurate input impedance and gain measurements of monopoles on a reduced size ground plane. Ideally, monopoles are measured with the antenna located on an infinite, perfectly conducting, ground plane. Practically, measurements are made on a test site with dimensions largely determined by the cost and availability of the space occupied by the site. Theoretical calculations show that the radius of a highly conducting ground plane should be at least 2λ , where λ = wavelength, for measuring the input impedance of 0.25λ monopoles. At 25 MHz, the lowest frequency considered here, such a ground plane would require a space at least 48 m (157 ft) in diameter. Model impedance measurements and calculations presented in this report imply that a space on the order of 10 by 11 m (33 by 36 ft) may be sufficient if the researcher uses 16 resistively-loaded wire radials to extend a 3.66 by 4.88 m (12 by 16 ft) solid metal ground plane. Measured insertion loss data acquired using a 1:5 scale model ground plane with resistively-loaded radials indicate that this area is sufficiently large for gain measurements as well. Measured and calculated monopole SWR and insertion loss on a full-scale ground plane verify the results of the model measurements.

Key words: gain measurement; impedance measurement; insertion loss; monopole antenna; reduced size ground plane; standard antenna; standing wave ratio.

1. INTRODUCTION

A gain-standard antenna, or simply standard antenna, is one having gain-pattern and input-impedance characteristics that are known with a small degree of uncertainty. Standard antennas are typically used in gain-transfer measurements to determine the gain of test antennas by comparing the signal level received by the test antenna to that received by the standard antenna when it replaces the test antenna [in a plane-wave field generated] on an antenna test range. For simplicity and accuracy, the standard antenna should have polarization and gain patterns similar to those of the test antenna. Therefore, a monopole standard antenna should be used to determine the gain of a monopole test antenna if the standard's input impedance and gain are to be accurately determined.

Accurately determining gain and impedance parameters for standard monopoles ordinarily requires that they be located on an electrically large, highly conducting ground plane [1,2]¹. The primary contribution of this report is applying a resistive loading technique [3] to make a small ground plane appear to be electrically larger than its physical dimensions would indicate.

2. MODEL MEASUREMENTS

2.1 Model Ground Planes

Model ground planes were centered on a 2.14 m (7.02 ft) diameter foamed polystyrene disk on top of a cart, placing the feedpoints 1.6 m (5.25 ft) above ground, on the underside of the ground plane. The relative dielectric constant of the disk is 1.03 to approximate free space. All measurements were made with a computer-controlled network analyzer system located on the cart below the center of this disk, thus minimizing cable lengths between the instrumentation and the antenna feedpoints.

In this report, the uncertainty of the standard monopole input impedance was determined by comparing measured and calculated impedance data for various ground plane configurations. The uncertainty of the standard monopole gain was determined by comparing measured and calculated insertion loss data for two

* Electromagnetic Fields Division, Center for Electronics and Electrical Engineering, National Engineering Laboratory.

identical monopoles at specified separation distances on a ground plane having resistively-loaded radials and designed to satisfy the input impedance requirements. Minimizing the difference between measured and calculated input impedance was assumed to be the most stringent design criterion for the ground plane. After the ground plane configuration was determined based on impedance measurements, the insertion loss data were measured.

2.2 Using Input Impedance to Determine Minimum Circular Ground Plane Size

Input impedance of thin linear monopoles was calculated by extrapolation from the data tables in [4], supplemented by data tables calculated using equations in [5]. The input impedance of thin linear monopoles over finite ground planes was obtained from the data in [6], "for monopole antenna[s] at the center of a perfectly conducting circular disk in free space."

Figures 1, 2, and 3 show the results of the initial set of impedance versus ground plane disk radius measurements performed with a single, fixed length, monopole chosen to duplicate that used for Richmond's

calculations at 900 MHz [6]. Monopole length and radius were 0.229λ (0.0763 m) and 0.003λ (0.001 m) respectively. The ground plane was a 0.18 cm thick aluminum disk having a 0.4λ (0.133 m) radius, centered on a sheet of aluminum foil lightly glued to the "free-space" disk. Input impedance was measured at 800, 900, and 1000 MHz using the following procedure. The overall diameter of the ground plane was reduced in size by removing successive rings of aluminum foil 0.2λ (0.067 m) wide until only the 0.4λ (0.133 m) radius disk remained. The measurements were made each time the annulus of foil was removed. Figures 4 and 5 show the foil covered disk at the start and midpoint of the measurement. Figure 6 shows the computer-controlled network analyzer located beneath the disk.

Excellent agreement between the data sets shown in figure 1 provides a high degree of confidence in the measured data, shown by the squares, and in the calculated data, both for an infinite radius ground plane, shown by the solid lines, and for finite radius ground planes in free space, shown by dashed lines connecting the triangles. Figures 2 and 3 show that the imaginary parts of the input impedance data do not converge to the solid lines as do those in figure 1. The measured or calculated data may not be as accurate for nonresonant monopoles as for resonant monopoles. Resonance is the frequency at which the imaginary part of the input impedance is zero for a monopole with a length near 0.25λ . For this test monopole, resonance occurs at 940 MHz.

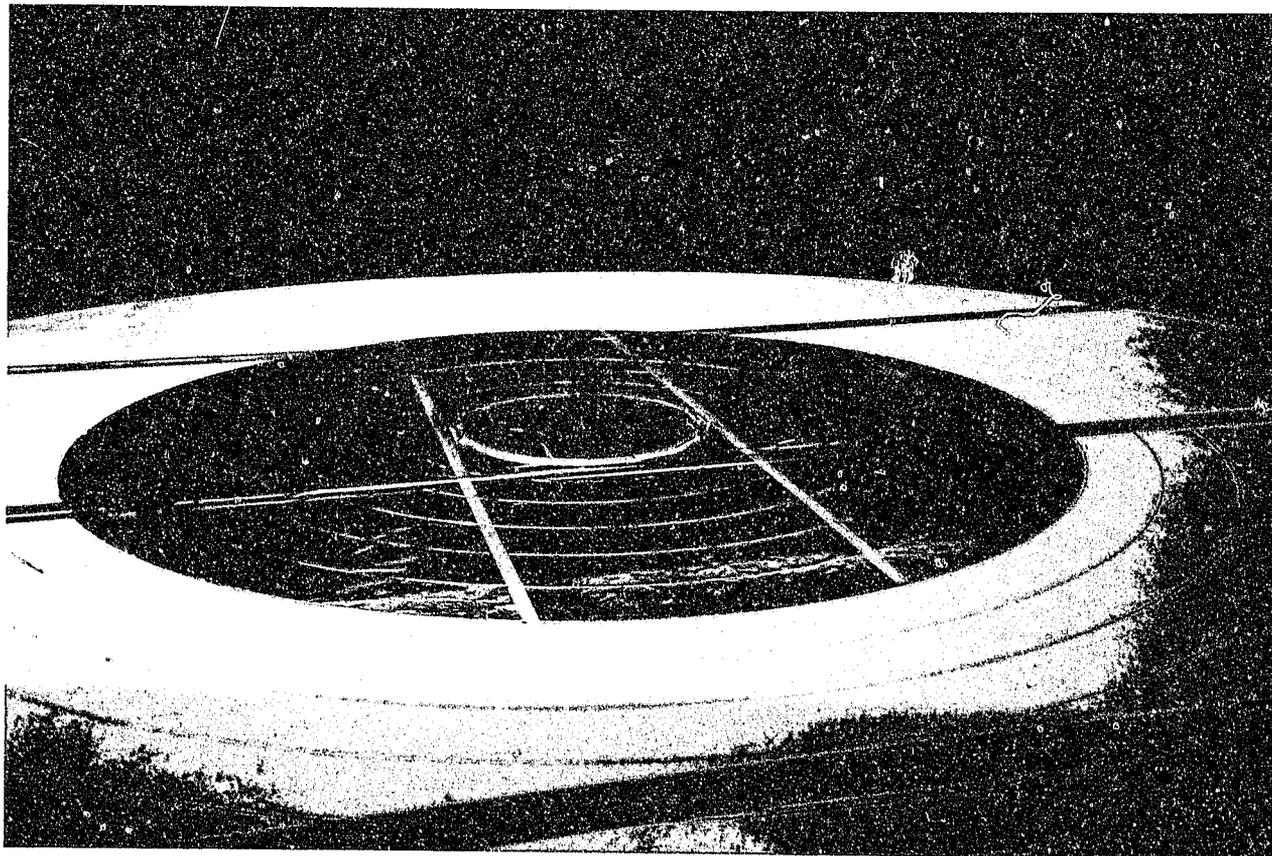

FIGURE 5. *View of the solid disk with eight annuli removed.*

FIGURE 6. *Underside of the disk showing instrumentation used for the measurements.*

The second set of measurements determined how well wire radials simulate a solid disk for impedance measurements. It was a duplicate of the first measurement except the aluminum foil ground plane was replaced by 16 evenly spaced #26 copper wire radials as shown in figure 7. Impedance was measured, a 0.2λ length was clipped from the end of each radial, and the measurements were repeated until only the 0.4λ

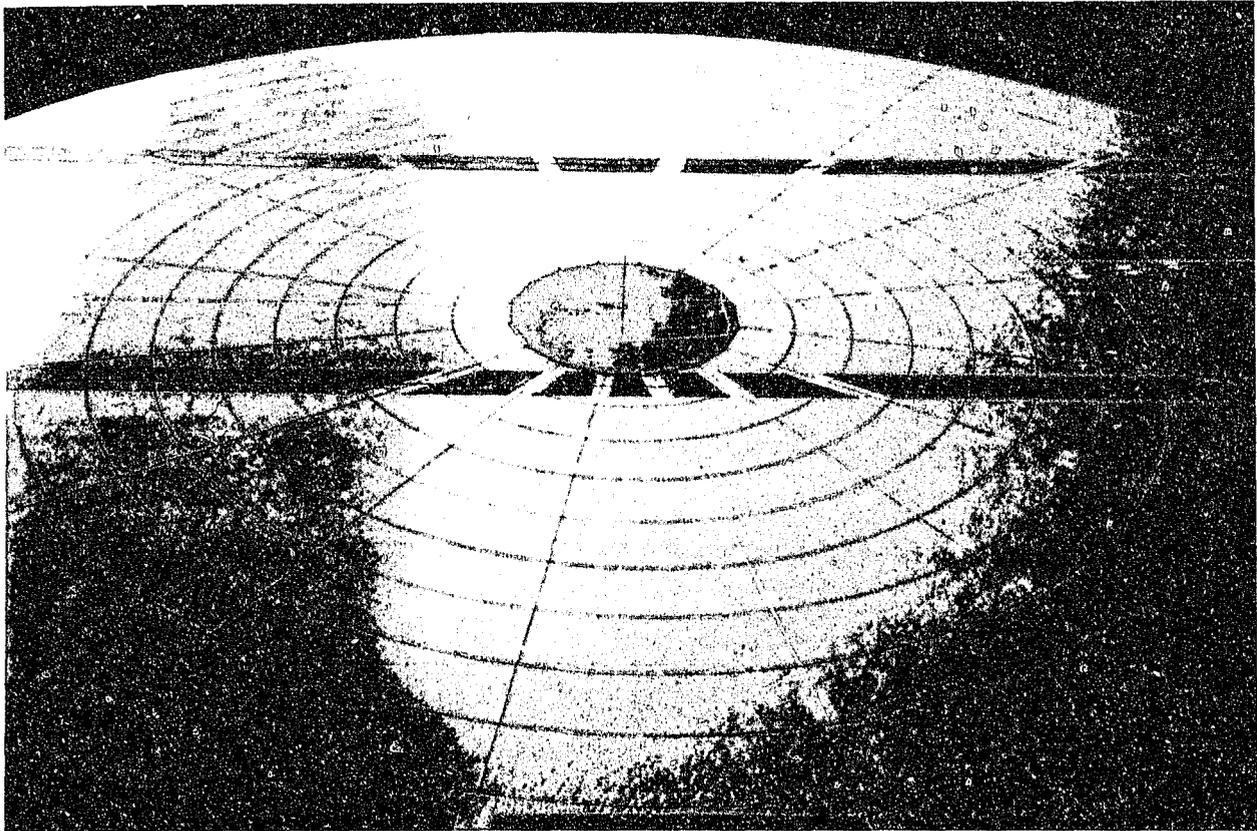

FIGURE 7. View of the wire disk model with 16 evenly-spaced wire radials.

radius disk remained. Figures 8, 9, and 10 differ substantially from the previous figures, and the data show no indication of convergence to the infinite radius, solid disk line. The choice of 16 radials is assumed to be a reasonable number that would be acceptable for use by industry personnel to fabricate temporary or permanent monopole test facilities.

The third set of measurements determined if Altshuler's resistively-loading technique [3] would work for this particular application. This technique alters the standing-wave current distribution on a linear wire antenna so that it is more like a traveling-wave distribution by inserting a $240\text{-}\Omega$ resistor 0.25λ from the open end of the wire. The resistor tends to terminate the wire in its characteristic impedance by minimizing the wave reflected at the wire end. The result is a large traveling wave with a small, superimposed standing wave on the wire. As viewed from the monopole terminals, the ground plane with resistively-loaded radials appears to be very large.

Eleven $240\text{-}\Omega$ resistors, with $0.2\text{-}\lambda$ (0.083-m) spacings starting at the open end of the wire, were placed serially in parallel with each wire radial. The wires bridging the outermost resistors were cut away. Monopole impedance was measured, then the outermost resistors and $0.25\text{-}\lambda$ sections of the radials were cut away, the sections of wire bridging the next outermost resistors were cut away, and the measurements were repeated until only the $0.4\text{-}\lambda$ radius disk remained. Figures 11, 12, and 13 show a considerable improvement in the behavior of the input impedance as a function of radial length, indicating that resistively-loaded radials do work for this particular application.

At this point, model measurements closely resembling the proposed gain and impedance measurements are performed using a resistively-loaded ground plane.

2.3 Model Ground Plane Configuration and Verification

Based on data in figures 11, 12, and 13, a model ground plane was fabricated assuming a 1:5 scale factor at the lowest design frequency of 30 MHz. The result is an aluminum sheet 0.4 by 0.6 λ (0.8 by 1.2 m) at 150 MHz with 16 240- Ω resistors soldered to brass screws located at equal angular spacings around the edge of the sheet. No. 26 wire radials, equal to the monopole length, were soldered to these resistors as shown in figure 14. Table 1 lists the pertinent data for the model configuration shown in figure 15 with the 0.424 m (1.39 ft) monopoles at the 0.4 m (1.3 ft) separation distance.

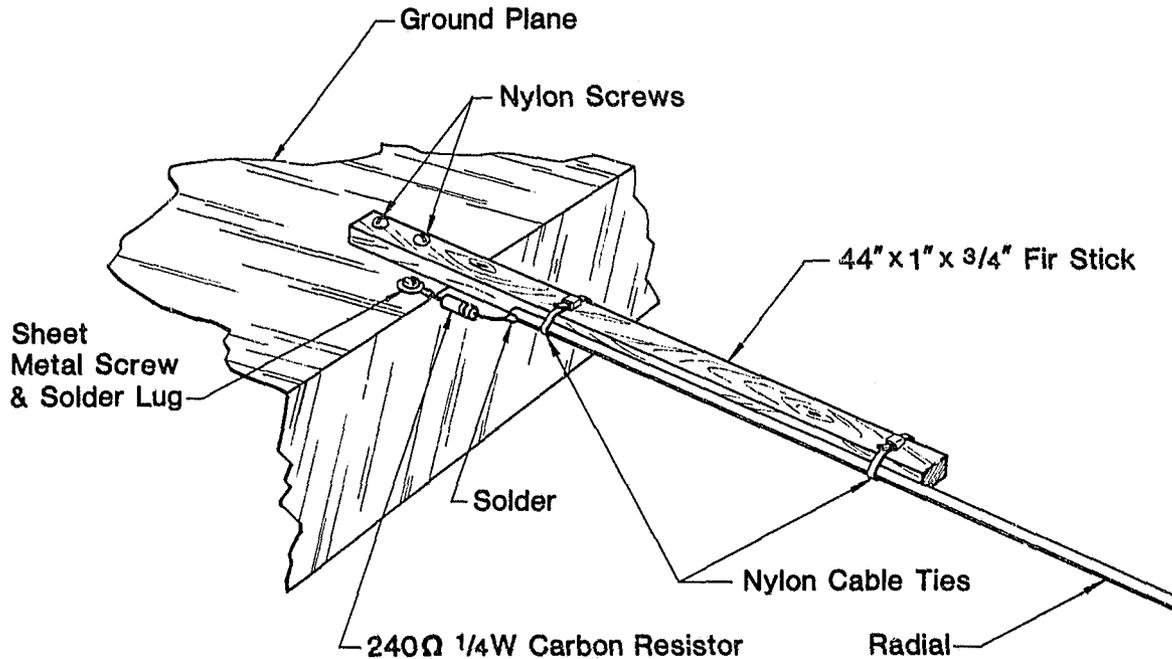

FIGURE 14. Attachment of the 240- Ω resistor between the ground plane and the wire radials.

TABLE 1. Test frequencies and monopole dimensions for the model ground plane.

Full scale frequency, MHz	Scale factor	Actual measured frequency band, MHz	Monopole length ^a , m	Monopole radius, cm	Resonant frequency, MHz
25-50	1:5	125-225 ^b	0.424	0.118	168
150-174	1:5	750-870	0.093	0.118	731
400-512	1:1	400-520	0.166	0.118	420
800-960	1:1	800-960	0.086	0.118	790

^a These lengths are the geometric means of the free-space values of $\lambda/4$ for the two frequencies listed in column 1, with the scale factor applied.

^b Two monopoles would have been a better choice for this wide band. Emphasis was placed on the more difficult, lower end of this band.

Model ground plane performance verification consisted of measuring input impedance (derived from the reflection coefficient) of a single monopole centered on the ground plane extended with resistively-loaded wire radials equal to the monopole length. Two identical monopoles were then placed 0.4 m (1.3 ft) apart on the ground plane's longer center line, and the insertion loss (obtained directly as the magnitude of the transmission coefficient) was measured. This measurement was repeated at an 0.8 m (2.6 ft) separation distance. Below 150 MHz, the 0.4 m (1.3 ft) distance is close to the $\lambda/2\pi$ distance from an electrically small monopole to the boundary between its reactive near-field and far-field regions. Far-field illumination conditions normally imposed for antenna tests are not required for the insertion loss because it is based on mutual impedance calculations requiring only a sinusoidal current distribution on the antennas. Since the gain

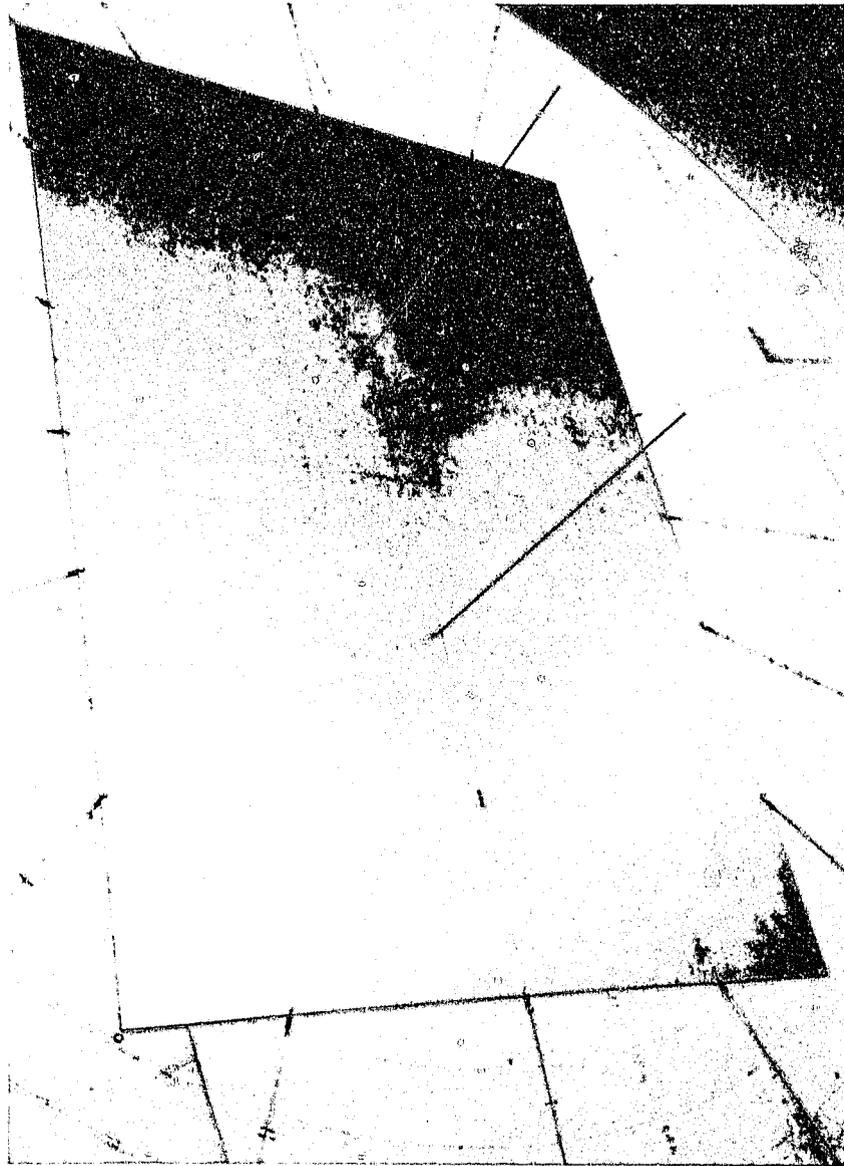

FIGURE 15. View of the model ground plane with the 0.424-m monopoles spaced 0.4 m apart. The 16 resistors and wire radials are evenly spaced in the angle around the edge of the rectangular aluminum sheet.

product of two antennas is an intrinsic part of insertion loss at far-field distances, gain of a test monopole relative to that of a standard monopole of similar length may be measured at near-field distances with an uncertainty based on the results of the insertion loss data.

Using a single monopole and loaded wire radial length for each set of measurements in a particular frequency band provides measured and calculated data indicating the bandwidth over which these measurements are valid. That is, the monopole and radials are electrically shorter below the monopole design frequency and longer above it. Measured and calculated input impedance versus frequency data are presented in figures 16 through 19. Agreement between these two sets of data is good, especially near the resonant frequency of the monopole, for all but the highest frequency band. Apparently the electrical spacing between the radials at the edge of the ground plane is too great, and reflections from the edge are occurring. This is shown in data in the next section by the cyclical variations in measured insertion loss data for this frequency band.

Voltage standing wave ratio, or SWR, is a scalar quantity related to input impedance that is commonly used to specify antenna performance. Figures 20 and 21 show SWR versus frequency, calculated using the impedance data from the preceding four figures. The agreement between measured and calculated data is quite good.

2.4 Insertion Loss and Gain Measurements

Substitution loss [7] is a relative measure of the transmission properties of two different waveguide junctions (two-ports or two-terminal-pair networks). It is the ratio, in decibels, of the power measured in a load with the initial two-port network in place, to the power measured in the same load with the final two-port network replacing the initial one in the transmission path. It is assumed that the generator and load characteristics remain the same for the two measurements. Insertion loss, a special case of substitution loss, is measured when the initial two-port network is perfect (a lossless, reflectionless, waveguide junction), and the reflection coefficients of the generator and load, ρ_G and ρ_L , are not necessarily equal to zero. The network analyzer measures the insertion loss between the terminals of two monopoles on the ground plane directly as the transmission coefficient. Initial load power is measured by the analyzer during self-calibration.

Attenuation, another special case of substitution loss, is measured when the initial two-port network is perfect and $\rho_G = \rho_L$ as well. It is assumed that the difference between the transmission coefficient and attenuation is accounted for in the error budget of the network analyzer. Insertion loss data was calculated using the computer program in appendix A based on the equations in NBS Technical Note 1089 [8] assuming $\rho_G = \rho_L$, and is given as a *positive* number. To avoid confusion, the term insertion loss rather than attenuation is used in this document.

Figures 22–25 show measured and calculated insertion loss versus frequency for two identical monopoles at two separation distances. The effects of the ground plane edges are shown by the cyclical variation of

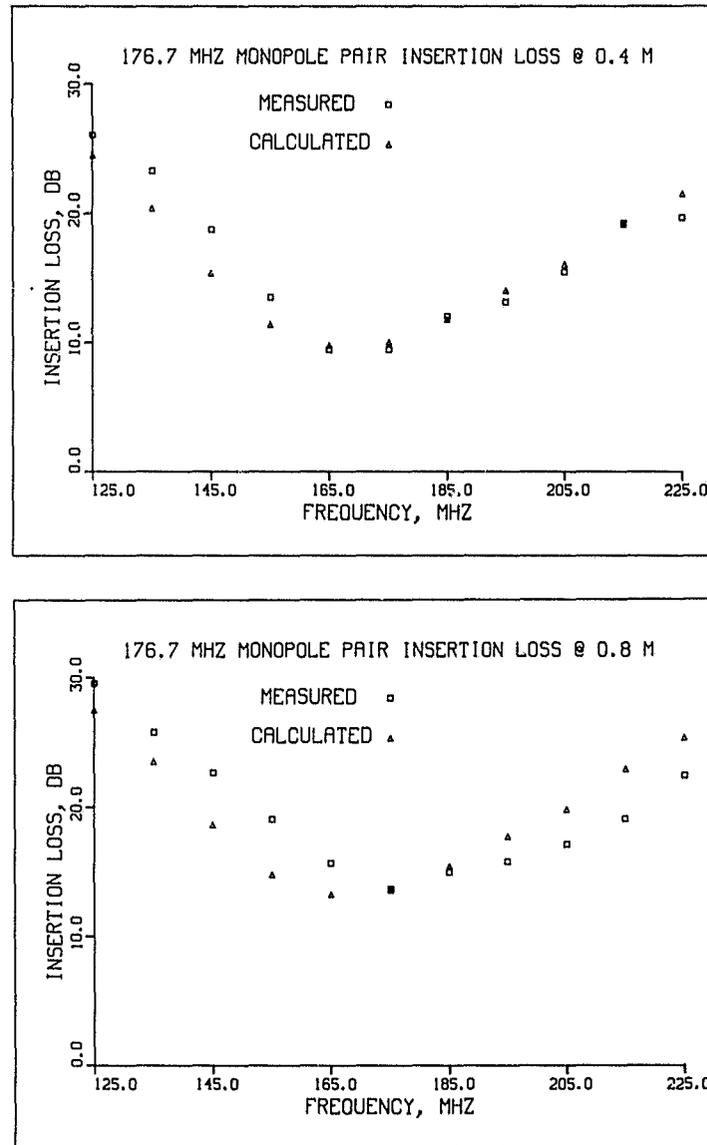

FIGURE 22. Insertion loss versus frequency for the 0.424-m monopole at 0.4-m and 0.8-m separation distances.

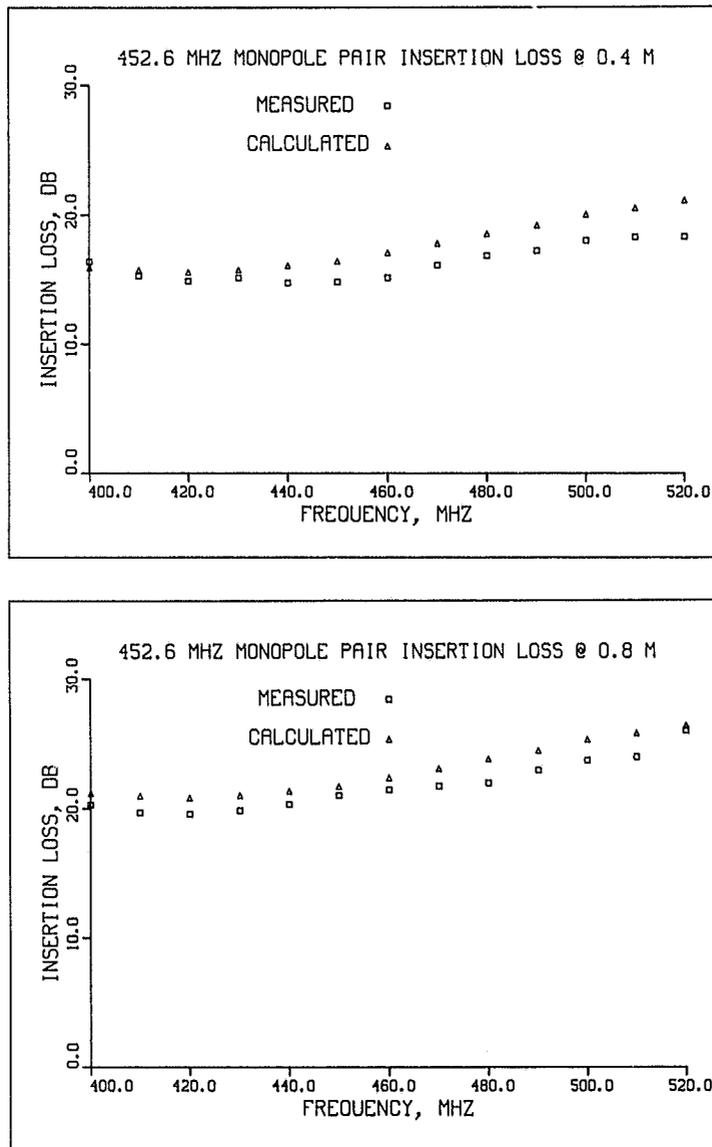

FIGURE 23. Insertion loss versus frequency for the 0.166-m monopole at 0.4-m and 0.8-m separation distances.

insertion loss with frequency that is most apparent at the two higher frequency bands. Generally, the 0.4 m (1.3 ft) separation distance results in a smaller difference between measured and calculated data. Note that insertion loss includes mismatch losses at the monopole terminals as well as the path loss between the monopoles. One-half of the difference between the measured and calculated data is a good estimate of the accuracy of realized gain of one of the identical monopoles assuming the ground plane is perfect. Realized gain is "The power gain of an antenna in its environment, reduced by the losses due to the mismatch of the antenna input impedance to a specified impedance" [9]. A 50-Ω specified impedance is assumed for all measured and calculated data in this document.

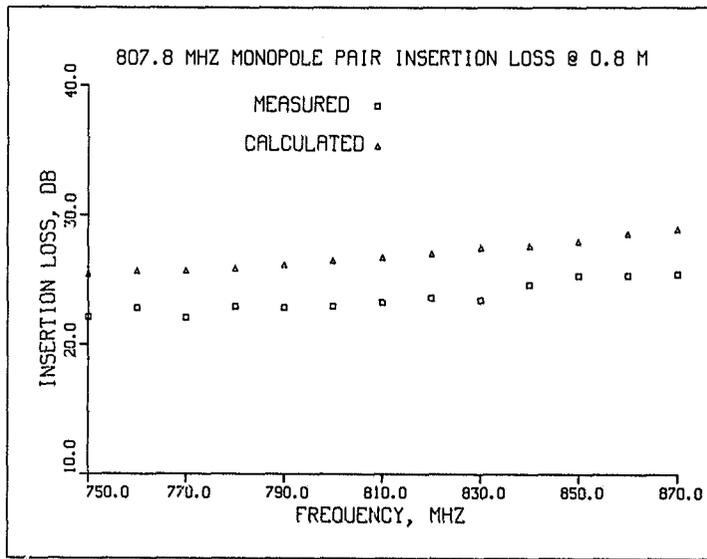

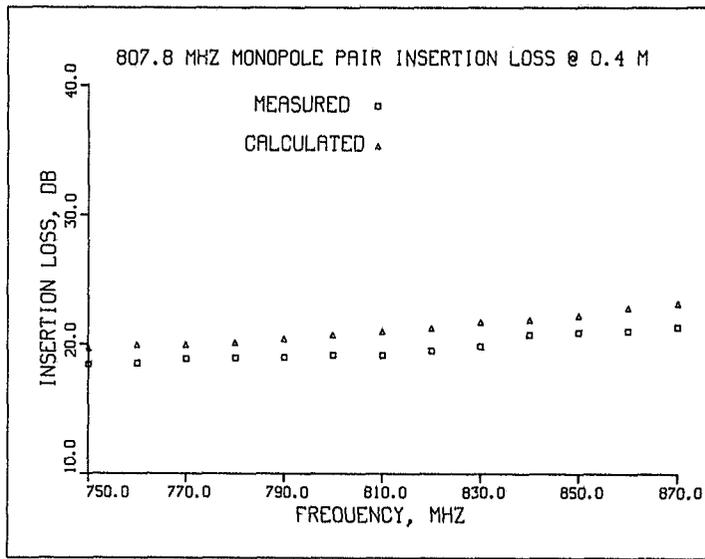

FIGURE 24. Insertion loss versus frequency for the 0.093-m monopole at 0.4-m and 0.8-m separation distances.

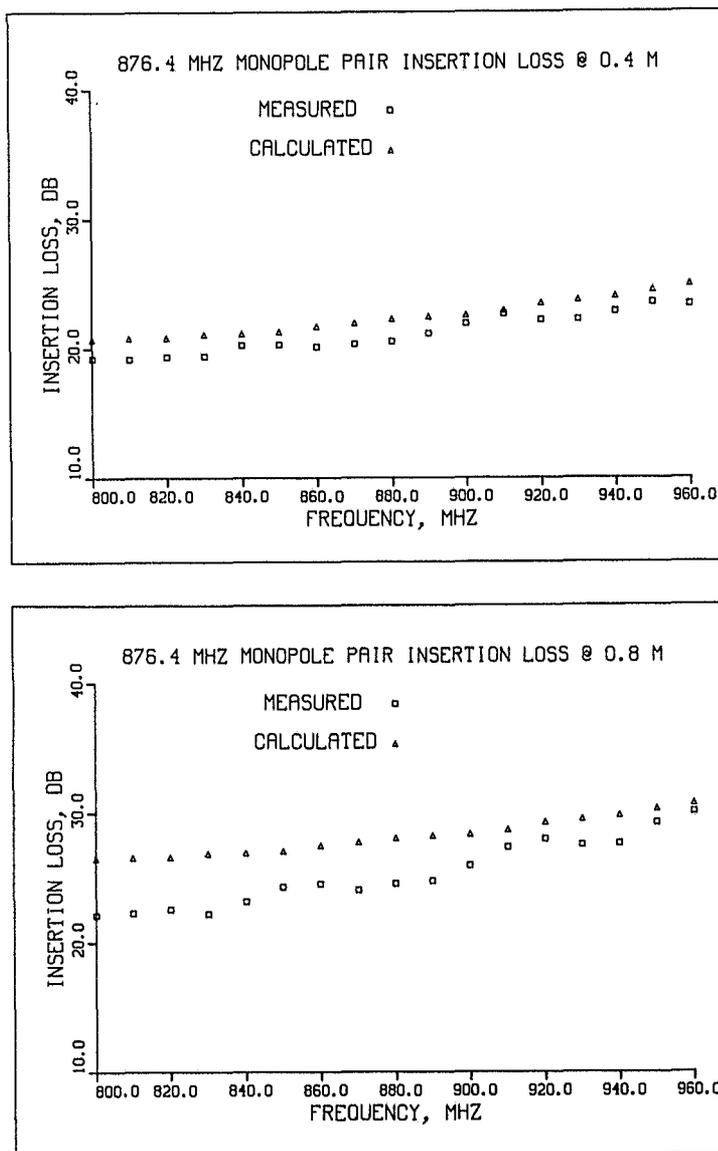

FIGURE 25. Insertion loss versus frequency for the 0.086-m monopole at 0.4-m and 0.8-m separation distances.

Realized gains for the model monopoles are presented in table 2. They were calculated using computer program GAIN77 in appendix B based on equations in NBS Technical Note 1098 [10]. Mismatch losses were subtracted from the power gains to obtain the realized gains. Mismatch losses versus frequency, calculated using the SWR data in figures 20 and 21, are presented in figures 26 and 27.

As can be seen in table 2, the realized gains of these monopoles are only slightly below the theoretical 4.79-dB value for a very thin 0.25λ monopole. The mismatch losses shown in figures 26 and 27 tend to be minimum near the resonant frequencies of the monopoles. Fixed frequency monopoles are usually adjusted in length to minimize this mismatch loss, although the gain changes only slightly when the length is adjusted.

TABLE 2. Calculated realized gains for the model monopoles^a.

Full scale frequency, MHz	Scale factor	Frequency used for gain calculation, MHz	Monopole length, m	Gain relative to isotropic, dB
35	1:5	176.7	0.424	4.54
161	1:5	807.8	0.093	4.21
452.6	1:1	452.6	0.166	4.36
876.4	1:1	876.4	0.086	4.15

^a All monopole radii are 0.118 cm.

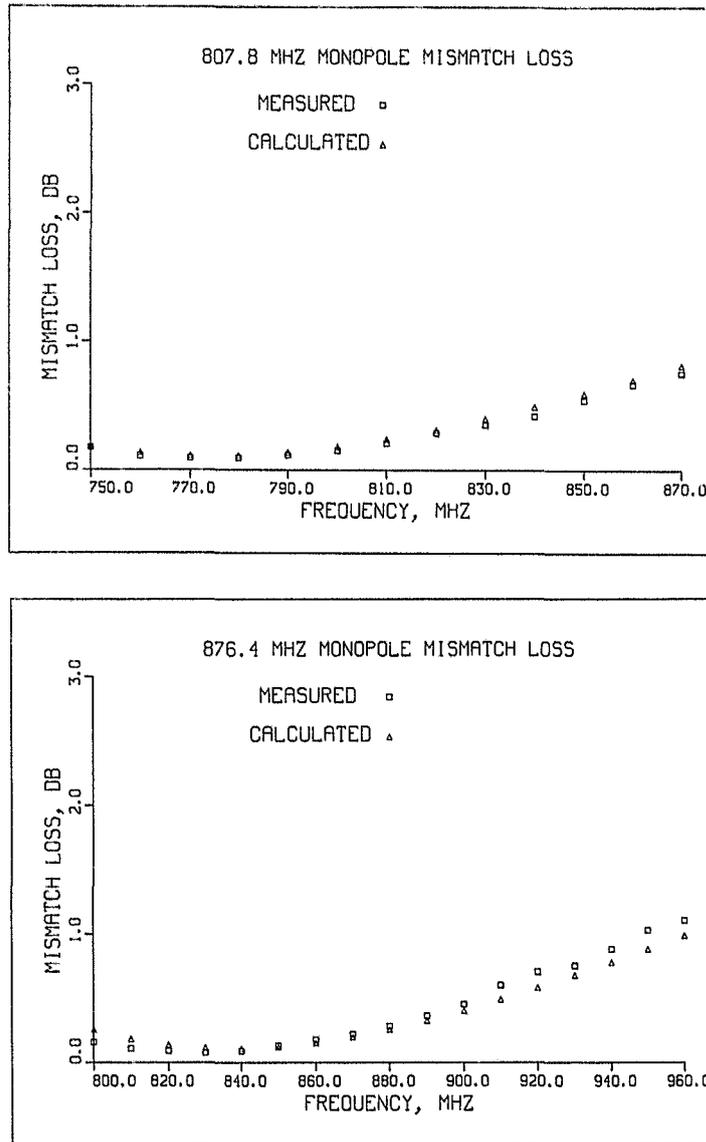

FIGURE 27. Mismatch loss versus frequency for the 0.093-m and 0.086-m monopoles on the model ground plane.

3. FULL-SCALE GROUND PLANE CONFIGURATION AND VERIFICATION

A 3.66 by 4.88 m (12 by 16 ft) wall-mounted microwave passive repeater forms the ground plane of the full-scale test facility. It is mounted horizontally with the attaching brackets supplied by the manufacturer. The height between the ground and the under surface of the ground plane and the feedpoints of the test antennas is 2.15 m (about 7 ft). This structure is designed to withstand 125 mph winds, and the surface flatness "Under no load . . . will be plus 0" and minus 1/8" where negative values indicate a concave surface," as specified by the manufacturer. A series of mounting holes for Type N panel jacks is located on a diagonal axis of the aluminum surface to allow insertion loss measurements at monopole-to-monopole separation distances of 0.06, 0.12, 0.18, 0.24, 0.36, 0.5, 1, 1.5, and 2 m. Sixteen resistively-loaded radials, having lengths equal to the monopole lengths, extend the electrical size of the ground plane at the frequencies below 175 MHz as discussed in section 2 of this document.

A computer-controlled network analyzer was used for all SWR and insertion loss measurements. Antenna SWR was measured with the test monopole mounted on the panel jack nearest the center of the ground plane. Figure 28 is a schematic representation of the ground plane and the test equipment is used for the full-scale measurements. Figure 29 is a photograph of the test facility with the 2.43 m (8 ft) monopoles and radials installed. White dielectric feedpoint assemblies may be seen in this photograph. They are used with the test antennas in the two lower frequency bands for mechanical support.

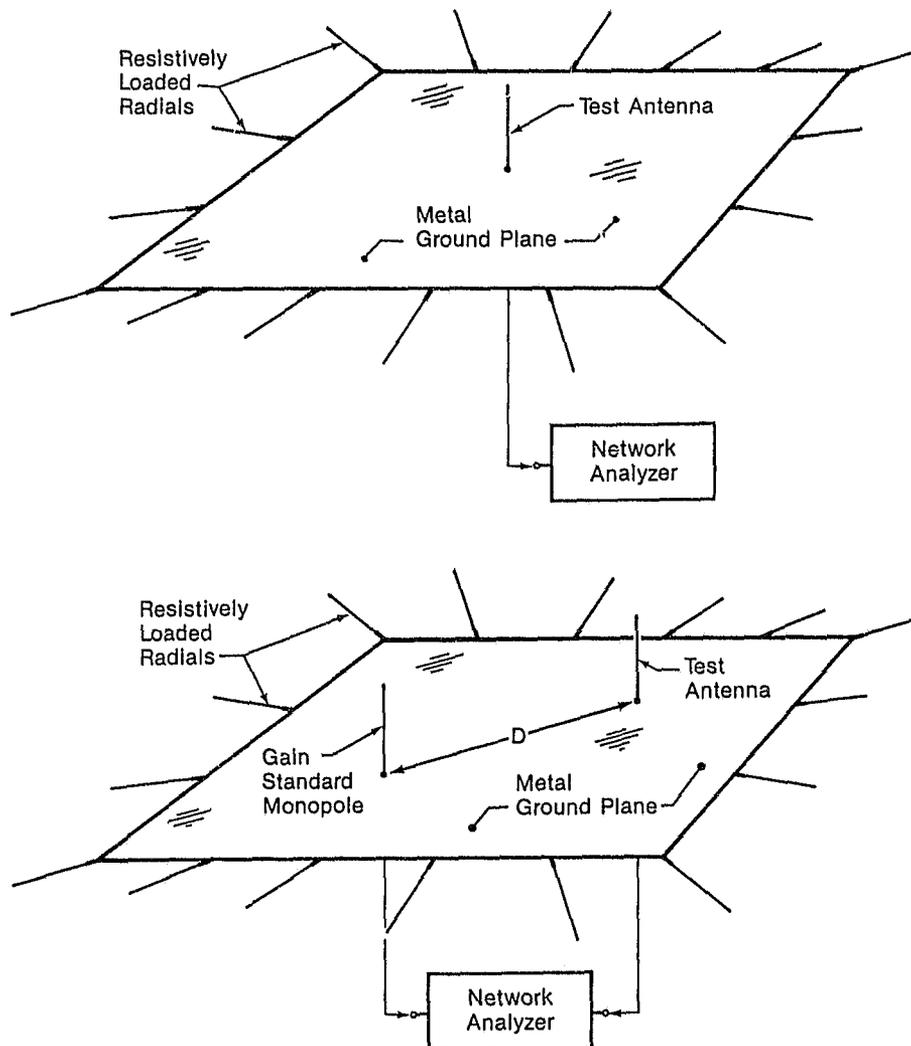

FIGURE 28. Schematic of SWR measurement, above; schematic of insertion loss measurement, below.

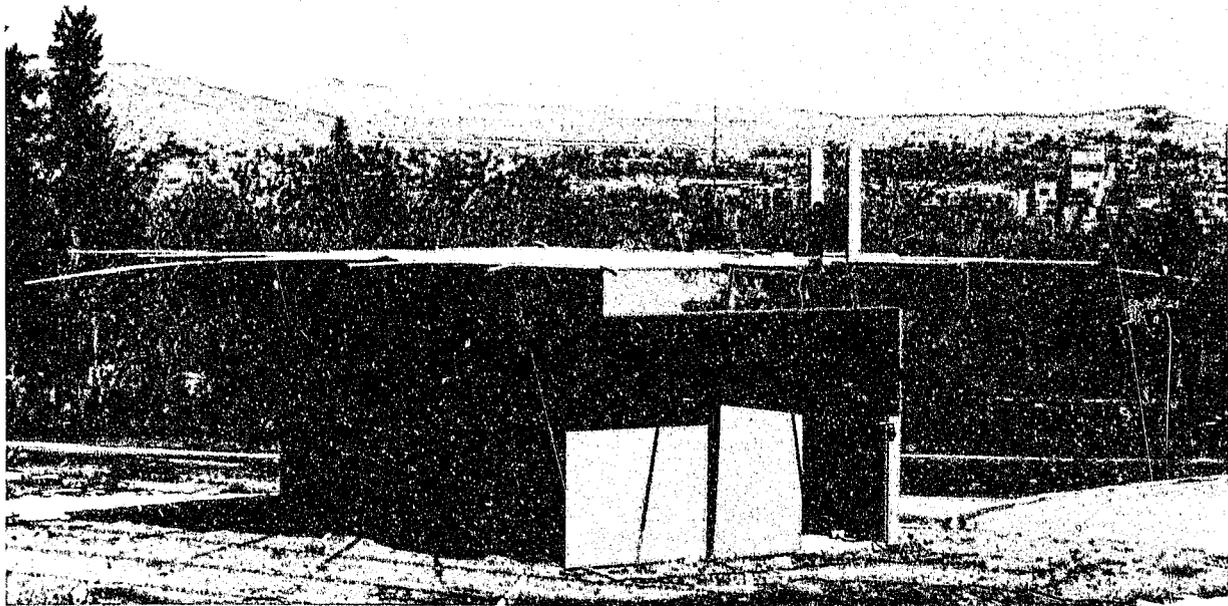

FIGURE 29. Photograph of the full-scale test facility with 2.43-m test antennas and resistively-loaded radials.

The characteristics of the monopole test antennas used for the full-scale measurements are given in table 3. These antennas are the gain-standard monopoles proposed for the NIJ Standard for Mobile Antennas [11].

TABLE 3. Test frequencies and monopole dimensions for the full-scale ground plane.

Frequency band, MHz	Length, m	Base radius, c	Tip radius, cm	Resonant frequency, MHz
25-35	2.43	0.5	0.125	29.65
35-50	1.72	0.5	0.27	41.5
150-174	0.445	0.24	0.24	157.5
400-510	0.156	0.24	0.24	435
805-865	0.0845	0.24	0.24	775

Full-scale SWR and insertion loss data are presented in figures 30-46. The difference between measured and calculated data gives a reasonable estimate of measurement uncertainty using the finite ground plane. SWR uncertainty is estimated to be the difference between the measured and calculated data. Uncertainty in monopole gain is estimated to be one-half the difference between the measured and calculated insertion loss data curves because the gain product of an identical monopole pair is an intrinsic part of the insertion loss. Measured data most closely matches the calculated data at the resonant frequencies of the monopoles, as it did for the model measurements.

The full-scale ground plane is large enough for measurements in the two highest frequency bands without resistively-loaded radials. None of the full-scale measurements show cyclical variations with frequency that would indicate reflections from the edges of the ground plane or a nearby building.
